HIGHLIGHTS GRAPHICAL ABSTRACT

- Clarithromycin of highest prevalence in sediment samples assessed.
- Low to moderate ecotoxicological risk for clarithromycin and sulphamethoxazole.
- Partitioning behaviour between sediment & water of importance to ecotox. risk.
- Ireland shows low concs. of antibiotics compared to similar studies worldwide.
- Ciprofloxacin also of potential ecotox. risk, but requires further assessment.

ABSTRACT

This study assesses the concentrations of a range of antibiotics in riverine and transitional sediments in Ireland. A selection of 12 macrolide, fluoroquinolone, sulphonamide, and diaminopyrimidine antibiotics were quantified in 80 grab surficial sediment samples from around Ireland, selected to investigate areas of potentially higher pollution risk (agriculture, aquaculture, industrial emissions, and wastewater emission points) as well as isolated areas where there are no known pollution sources. Several of the macrolides and sulphonamides/trimethoprim were generally detected more frequently above limits of quantification (LoQ). Fluoroquinolones, while frequently detected above limits of detection (LoD), concentrations were mostly below method LOQs. The most prevalent antibiotic detected was clarithromycin, found at the highest mean concentration (6.65 ng/g) and detected in ~90 % of samples. Comparing levels of quantified antibiotics to levels reported internationally, Ireland is at the lower end for all quantified antibiotics. This is with the notable exception of clarithromycin, which is higher than levels found in comparable studies in Italy, Spain, France, and Argentina. Higher levels of

total antibiotics (49.3 \pm 24.7 ng/g) were found to be present immediately adjacent to wastewater emission points while moderate degrees of contamination $(9.0 \pm 9.7 \text{ ng/g})$ were also linked to wastewater, aquaculture, or agricultural pressures. Based on risk quotients calculated from available sediment PNECs taken from the NOR-MAN ecotoxicology database, clarithromycin was also the only compound to be present at concentrations indicative of a "moderate" degree of environmental risk, with most of the remaining falling below this threshold. Ciprofloxacin was ostensibly found to be of a "high" degree of environmental risk; however, this is based on only a single sample quantified above the LoQ. Overall, antibiotic sediment concentrations suggest a low ecotoxicological risk for most of the target antibiotics, although clarithromycin, ciprofloxacin, and sulfamethoxazole warrant further monitoring in sediments. A final notable finding is the differences in partitioning behaviour of antibiotics between water and sediment: clarithromycin is more likely to be detected in sediment while sulfamethoxazole partitions more to water. Such partitioning behaviour should therefore be taken into consideration for any subsequent monitoring programmes.

1. Introduction

Antimicrobials encompass a wide range of chemicals which act against various microbes such as fungi, viruses, and bacteria. Under this umbrella, antibiotics are specifically used to treat bacterial infections in humans and animals. However, the high usage of antimicrobials has resulted in increased instances of antimicrobial resistance (AMR) whereby continued exposure of microbes to antimicrobials results in the growth and proliferation of drug-resistant strains (WHO, [2022a\)](#page-7-0). One of the major drivers of AMR is overuse of broad-spectrum antibiotics such as azithromycin, clarithromycin, ciprofloxacin, and sulfadiazine and there are a myriad of factors – from a lack of access to suitable medications, to overburdened healthcare systems, to fears of litigation for under-treating or under-prescribing medication – which are suspected to have contributed to the over-prescription of antibiotics in particular ([Tarrant](#page-7-0) et al., 2021). Though undoubtedly versatile and effective, their overuse has been directly linked to the propagation of more resistant strains of bacteria, such as the excessive use of the methicillin inadvertently leading to the proliferation of methicillin-resistant *Staphylococcus aureus* ([Harkins](#page-7-0) et al, 2017), as well as similar instances in other common bacterial infections such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Neisseria gonorrhoea* [\(WHO,](#page-7-0) 2019). Besides the risk of promoting the growth of resistant bacterial strains, the release of these antibiotics into the environment is also of direct ecotoxicological concern: adversely affecting photosynthesis and mitochondria in plants as well as delaying germination and reducing biomass in agricultural soils [\(Polianciuc](#page-7-0) et al, 2020).

Assessing the modes of release of antibiotics into the environment and assessing the degree of risk to ecological systems (including the proliferation of AMR) is an under-studied topic ([Wang](#page-7-0) et al, 2023). Environmental pollution of antibiotics is recognised by the World Health Organisation as "*… critical for combatting rising levels of drug resistance*" (WHO, [2022b](#page-7-0))*.* The presence of antibiotics in environmental matrices such as sediments has been linked to increasing instances of antibiotic-resistant bacteria (BIO IS, [2013;](#page-6-0) [Polianciuc](#page-7-0) et al, 2020; [Wang](#page-7-0) et al, [2023\)](#page-7-0), while their presence in water and sediment phases has also been linked to the distribution of antibiotic-resistant genes and mobile genetic elements [\(Chen](#page-7-0) et al, 2019; Wu et al, [2023](#page-7-0)). The bioavailability of these antibiotics is a major factor in their release into the environment. For example, ciprofloxacin has reported uses in cattle as well as domestic animals as a broad-spectrum antibiotic to treat a variety of infections [\[Mercer,](#page-7-0) 2022a; O'[Sullivan](#page-7-0) et al, 2019; [Papich,](#page-7-0) 2017]. However, the bioavailability in cattle and domestic animals has been shown to be less than 20 %, leading to a large non-metabolised fraction being excreted in waste [\(Mercer,](#page-7-0) 2022a). These bioavailabilities can vary widely depending on their class and the animal or human being treated [\(Chakwenya](#page-7-0) et al., 2002; [Pitman](#page-7-0) et al., 2019; [Mercer,](#page-7-0) 2022b). The release of antimicrobials into the environment is largely attributed to the discharge of wastewater following administration to humans and animals [\(Carvalho](#page-7-0) and Santos, 2016).

In Ireland, roughly three times as many antibiotics are used in human healthcare compared to veterinary applications (O'[Sullivan](#page-7-0) et al, 2019). β-Lactam antibiotics such as penicillin constitute most antimicrobial use in humans in Ireland, while tetracyclines are dominant in animals, predominantly from use in the agricultural sector; the remaining share of antibiotics used in both humans and animals are spread among a wide array of antibiotics including diamino-pyrimidines, fluoroquinolones, lincosamides, macrolides (second most utilised in humans), and sulphonamides (second-most utilised in animals) (O'[Sullivan](#page-7-0) et al, 2019). While penicillins dominate the market and relatively large fractions are shown to be excreted in urine after ingestion [\(Morris](#page-7-0) et al, 2008; [Bryskier,](#page-6-0) 2005), they are thought to be of low environmental concern due to their short half-lives in aqueous environments and susceptibility to several modes of degradation [\(Hirsch](#page-7-0) et al, 1999; [Monahan](#page-7-0) et al, [2022\)](#page-7-0). By contrast, macrolides, fluoroquinolones, and sulphonamides (the lattermost typically used in conjunction with trimethoprim [\(Kemnic](#page-7-0) and [Coleman,](#page-7-0) 2022)) are shown to be much more environmentally persistent and resistant to biodegradation ([Morris](#page-7-0) et al, 2008). A recent study in Ireland concluded that macrolides were expected to be of the highest environmental risk, with quinolones, pyrimidines, tetracyclines, and sulphonamides expected to represent lower risk. ([Rodriguez-Mozaz](#page-7-0) et al, [2020](#page-7-0)). This study further shows that a selection of these antibiotics are present in the effluent from Irish wastewater treatment plants (WWTPs) while O'Flynn [\(2024\)](#page-7-0) report on their presence in river water.

To accompany this previous data of antibiotics in surface water and WWTP effluent, this study aims to investigate the presence of a selection of antibiotics in Irish sediments in order to: provide an estimate of the degree of risk to the Irish environment based on their measured concentrations and ecotoxicities; investigate the partitioning behaviours of selected antibiotics in sediment and water; attempt to identify prominent sources of environmental release of antibiotics; and identify priority pollutants for further investigation and further monitoring. Presented here is the first ever study of antibiotics in Irish sediments, as well as (to the authors' knowledge) the largest ever study of concentrations of antibiotics in inland and transitional sediments in Europe, and the first to assess levels of difloxacin and levofloxacin in sediments.

2. Materials and methods

2.1. Antibiotics under investigation

As outlined in *Section 1*, the antibiotic classes of particular relevance to environmental contamination in Ireland are fluoroquinolones, macrolides, and sulphonamides (along with their common synergist, trimethoprim). Included in the list of analytes are the following antibiotics: azithromycin, clarithromycin, and erythromycin which had been listed as "watch-list" chemicals under the Water Framework Directive (WFD) 2000/60/EC and for which exist draft environmental quality standards per the Environmental Quality Standards (EQS) directive 2008/105/EC [\(SCHEER,](#page-7-0) 2022a, [2022b](#page-7-0), [2022c\)](#page-7-0); trimethoprim, sulfamethoxazole, ciprofloxacin, and ofloxacin, which have been or are currently watch-list chemicals under the WFD (EU [2015](#page-7-0), [2018](#page-7-0), [2020](#page-7-0), [2022\)](#page-7-0); as well as difloxacin, enrofloxacin, levofloxacin, roxithromycin, and sulfadiazine, additional fluoroquinolones, macrolides, and sulfadiazines which are commonly-used in Irish veterinary and human health applications (O'[Sullivan](#page-7-0) et al, 2019) (*SI 1*).

2.2. Sample collection

A total of 80 sediment samples were collected from inland $(n = 61)$ and transitional ($n = 19$) waters across Ireland in 2023 for analysis of the antibiotics outlined above. The full details of this sampling campaign are reported elsewhere (*[Sharkey](#page-7-0) et al, 2024*). Briefly, approximately 1 kg aliquots of sediments were collected from inland and transitional sites (*SI 2*) prior to homogenisation, wet sieving to a maximum grain size of 2 mm, and freeze-drying under a 0.133 mBar vacuum to a uniform temperature of − 40 ◦C over a period of approximately six days. Samples were then sealed using parafilm and screw-top caps, and stored at − 20 ◦C prior to analysis. Additional metadata for statistical analysis (*Section 2.6*) including water body type and river flow speed were obtained from the Environmental Protection Agency's Geographic Information System ([https://gis.epa.ie/EPAMaps/Water\)](https://gis.epa.ie/EPAMaps/Water), while population densities at sampling locations were obtained from the central statistics office ([https://www.cso.ie/\)](https://www.cso.ie/).

2.3. Chemicals and standards

Fourteen individual native antibiotic standards (erythromycin, clarithromycin, roxithromycin, azithromycin, lincomycin, trimethoprim, sulfamethoxazole, sulfadiazine, norfloxacin, enrofloxacin, ofloxacin, levofloxacin, difloxacin, and ciprofloxacin) and six labelled standards (d₃-erythromycin, d₃-azithromycin, d₄-sulfamethoxazole, d₃ofloxacin, d_8 -ciprofloxacin, and d_3 -difloxacin) were supplied by Wellington Laboratories (Guelph, Canada).

SPE columns Oasis HLB 6 cc, 200 mg (Waters, USA), optima grade methanol, optima grade acetonitrile (ACN), optima grade water (Fisher Scientific, Loughborough, UK), citrate buffer solution 0.2 M pH 4 (Generon Ltd, Slough, UK), Na2EDTA Molecular Biology Grade (Promega UK, Chilworth, UK), and formic acid (≥98%) (Sigma-Aldrich, Burlington, USA) were purchased for extraction and analytical procedures.

2.4. Sample extraction

Antibiotics laboratory extraction and clean up method was applied to sediment samples involved accurately weighing ca. 2 g aliquots of sample treated with 50 ng isotopically labelled antibiotics $(d_3$ -erythromycin, d_3 -azithromycin, d_4 -sulfamethoxazole, d_3 -ofloxacin, and d_8 -ciprofloxacin) as internal (or surrogate) standards (IS). The samples were extracted using 3 sequential cycles of ultrasonication and vortexing using 5 mL citrate buffer (pH 4) with ACN (1:1, v/v) and 0.2 g of Na2EDTA. The extract was centrifuged at 3000 RPM for 10 min and the three supernatants were combined (15 mL total) and filtered through a 0.7 μm glass fibre filter (GF/F, Whatman) and diluted to 60 mL with water (optima grade). The diluted samples were then loaded onto preconditioned and equilibrated Oasis HLB SPE cartridges (200 mg, Waters, USA), washed with 10 mL of optima grade water, then dried under vacuum for ca. 20 mins to remove excess water. Samples were then eluted using 10 mL methanol with 0.1 % formic acid under light vacuum. The eluent was gently evaporated to incipient dryness under a gentle stream of nitrogen and reconstituted in 0.5 mL water/methanol with 0.1 % formic acid $(1:1, v/v)$ (optima grade) with 10 ng of recovery determination (or syringe) standard (RDS, d₃-difloxacin). The final 0.5 mL extract was transferred to a 1.5 mL amber vial and stored at − 20 ◦C until analysis via Ultra High-Performance Liquid Chromatography Time of Flight Mass Spectrometry (UHPLC-TOF-MS).

2.5. Instrumental analysis

A 5 μL aliquot of the sample extract was injected into a Sciex Exion UHPLC coupled to a Sciex 5600+ triple TOF MS fitted with an Accucore RP-MS (internal diameter: 2.1; length: 100 mm; particle size: 2.6 μm, Thermo Scientific). Using a flow rate of 0.4 mL/min, a mobile phase gradient was ramped from 98 % Mobile Phase A (2 mM ammonium acetate in optima grade water), 2 % mobile phase B (optima grade MeOH with 0.1 % formic acid) to 98 % mobile phase B over 11 min. This was held for 1 min before equilibrating back to 2 % mobile phase B for 3.5 min. The triple TOF MS was operated in MS/MS mode equipped with a Turbo V source operated in positive mode using electrospray ionisation at a voltage of 5500 V. The curtain gas was set at 25 psi, whilst the nebuliser gas (source gas 1) was set at 45 psi and the drying gas (source gas 2) at 45 psi. Five-point calibration was conducted using standard solutions of known concentration (see *SI* 3). The collision-activated dissociation (CAD) gas was set to medium and the temperature to 350 ◦C. Manual mass calibration was performed on the instrument prior to the injection of each batch of samples using a Sciex calibrant delivery system (CDS) to ensure a starting mass accuracy of *<*1 ppm. An automated calibration was also performed after every 5 injections to ensure ongoing mass accuracy throughout each run. Quantification of individual antibiotics was performed in Multiquant 3.0.2 using appropriate mass transitions (for details see *SI 4*).

2.6. Data analysis and risk assessment

For comparisons of mean concentrations determined with various metadata recorded (Inland vs transitional waters, population density, and river speed), non-parametric statistical tests are used as data do not follow a normal distribution. For two sample means Mann-Whitney U tests are used while for greater number, Kruskal Wallis H tests are used (confidence interval of 95 %, Significance Level (p) of 0.05). Where data are recorded to be below the limits of detection (LoQ), proxy values are determined using (LOQ x Detection Frequency). Where appropriate and noted, graphed data omit data points below LOQ and reports the statistical metrics along with the detection frequency for the relevant parameter(s).

Risk Quotients (RQs) are employed to evaluate ecotoxicological risks for targeted compounds in sediment samples collected in inland and transitional sediments in 2023. RQs were calculated per the following equation:

RQ ⁼ *MEC*⁹⁵ *Lowest PNEC*

where MEC₉₅ is the 95th percentile of the maximum measured environmental concentration and lowest predicted no-effect concentration (PNEC) in sediments are taken from the Norman Ecotoxicology Database ([www.norman-network.com/nds/ecotox\)](http://www.norman-network.com/nds/ecotox). Degree of risk is assessed based on resulting risk quotient: RQ *>* 1 – high risk; 1 *>* RQ *>* 0.1 – moderate risk; RQ *<* 0.1 – low risk ([Carvalho](#page-6-0) et al, 2015).

3. Results and discussion

3.1. Concentrations of antibiotics in Irish sediments

No statistically significant differences were seen in inland sediment concentrations compared to transitional sediment concentrations in this study (*SI 6*); therefore, for the purposes of reporting and statistical analysis, data will be considered as a single dataset with $n = 80$ samples. [Table](#page-3-0) 1 reports summary statistics for the target antibiotics in inland and transitional sediment samples. At least one antibiotic was detected at concentrations above the method LoD in all samples, and at least one antibiotic was quantified in 77/80 samples at concentrations above the LoQs. The detection frequency differed significantly across the analytes with ciprofloxacin and enrofloxacin being quantified in only one sample apiece, while clarithromycin was detected in 87.2 % of samples. Only a few analytes were detected at a relatively high (*>*20 %) detection frequency: Clarithromycin was by far the most frequently detected (87.2

Table 1

Summary statistics of concentrations (ng/g) of antibiotics quantified in inland and transitional sediments collected from locations around Ireland in 2023. "n" = number of samples analysed (note: antibiotics were not quantified in some samples due to interference). "DF" = percentage of samples detected above the limit of quantification. "Range" shows the Limit of Quantification for each substances as the minimum value. "PNEC" - Predicted No-Effect Concentration. "% (RQ *>* 0.1)" percentage of samples above a Risk Quotient of 0.1 (i.e. of 'moderate' risk or higher – see Section [3.3\)](#page-4-0).

| Antibiotic | n | Mean | LOQ | Median | Range | DF (%) | PNEC | % (RQ > 0.1) |
|------------------------|----|---------|-------|---------|----------------|--------|-------------|-----------------|

| Roxithromycin (ROX) | 78 | $<$ LOO | 0.333 | $<$ LOO | $<$ LOO - 4.46 | 7.69 | 129 | Ω |
| Sulfamethoxazole (SME) | 80 | 0.077 | 0.047 | $<$ LOO | $<$ LOO - 0.33 | 33.3 | 3.97 | 2.50 |
| Sulfadiazine (SDI) | 78 | $<$ LOQ | 0.074 | $<$ LOQ | $<$ LOO - 0.98 | 8.97 | 7.28 | $\mathbf{0}$ |

%), followed by azithromycin (38.8 %), sulfamethoxazole (33.3 %), and trimethoprim (20.5 %). There were similarly no statistically significant correlations based on relative population size of the surrounding area where samples were collected nor the relative water speed (*SI 7, 8*).

As outlined in *[Section](#page-1-0) 1*, the discharge of wastewaters originating from humans and animals is suspected as being the major source of antibiotics entering the environment. This conforms with results garnered here with samples collected in the immediate vicinity of wastewater emission points (*<*0.1 km) showed levels of total antibiotics $(49.3 \pm 24.7 \text{ ng/g})$ which were significantly higher ($p < 0.01$) than those taken well-isolated ($<$ 5 km) from emission points (4.7 \pm 3.8 ng/ g). Two notable exceptions of these "isolated" samples showed comparatively high concentrations of clarithromycin (*>*10 ng/g): the first river site (*SI 2.1* – Sample 18) being noted by the EPA as having significant aquaculture pressures, where antibiotics are commonly used ([Cherian](#page-7-0) et al, 2023); and the other (*SI 2.1* – Sample 64) as having significant agricultural pressures, where antibiotic residues from cattle treatment as well as run-off from wastewater-derived biosolids ([Rodriguez-Mozaz](#page-7-0) et al, 2020; Uisce Éireann, 2024) used on farmland could lead to environmental contamination. Samples in an intermediate range from wastewater emission points (0.1–5 km) have more moderate degrees of contamination with a broader range (9.0 ± 9.7 ng/g) with the higher concentrations coinciding with high population equivalent, wastewater treatment emissions and agricultural or aquaculture pressures [EPA, [2024](#page-7-0)].

3.2. Comparison of antibiotics in different environmental matrices in Ireland

Next to penicillins, macrolides (such as clarithromycin) were likely to present the greatest risk to the Irish environment based on the ecotoxicological risk, due to extensive use in humans, and its relatively high half-life in sewage entering the environment (mean of 46.91 days; [Monahan](#page-7-0) et al, 2022). The comparatively high use rate in humans is reflected in results reported herein showing that clarithromycin and, to a lesser extent, azithromycin, are dominant in sediment samples. However, other data reported from Ireland may point to uptake into different environmental compartments being a significant consideration. Fig. 1 shows a comparison between the relative levels of five antibiotics re-ported in sediments (this study), river waters (O'[Flynn,](#page-7-0) 2024), and WWTP effluents ([Rodriguez-Mozaz](#page-7-0) et al, 2020). Effluents from WWTP broadly conform to reported antimicrobial usage: the macrolides clarithromycin and azithromycin being dominant (high usage in humans and moderate usage in animals), with trimethoprim/sulpha-antibiotics

Fig. 1. Relative abundance of antibiotics in Irish sediments (this study) compared to composition of river water (O'[Flynn,](#page-7-0) 2024) and WWTP effluents [\(Rodriguez-Mozaz](#page-7-0) et al, 2020). Stated years refer to the year of collection.

(major use in animals, very minor use in humans) and fluoroquinolones (minor use in both humans and animals) showing up secondarily. Comparing levels and distribution in the environmental compartments, clarithromycin is much more abundant in sediment samples while sulfamethoxazole is more prevalent in water samples. This is reflected in the octanol: water partitioning coefficients (Log K_{OW}) of the compounds, with sulfamethoxazole being much more hydrophilic (Log K_{OW} = 0.7–0.89) than clarithromycin (Log $K_{OW} = 1.7$ –3.16) [\(https://pubchem.](https://pubchem.ncbi.nlm.nih.giv/gis.epa.ie/EPAMaps/Water) [ncbi.nlm.nih.gov/](https://pubchem.ncbi.nlm.nih.giv/gis.epa.ie/EPAMaps/Water)). The low ecotox. risk for the majority of antibiotic residues assessed herein may therefore not translate to an equivalent risk in other environmental compartments. The partitioning behaviour of antibiotics should therefore be taken into consideration for further antibiotic residue assessment and monitoring.

3.3. Ecotoxicological implications of concentrations of antibiotics in Irish sediments

For the majority of samples analysed, antibiotic concentrations were below the "low risk" threshold when compared to available sediment PNECs, with the exception of clarithromycin and sulfamethoxazole where several samples each were shown to be in the "moderate" risk category (0.1 *<* RQ *<* 1). Azithromycin, enrofloxacacin and ciprofloxacin were similarly in the low risk category, with only a single sample apiece being above the 0.1 RQ threshold for low risk (Fig. 2; Table 2). However, as outlined in *[Section](#page-3-0) 3.2*, the matrix into which antibiotics partition may be a significant factor in relative risk to different compartments. For example, based on results from O'Flynn [\(2024\)](#page-7-0) and the results of his study on surface water along with PNECs in surface water from the NORMAN database: levels of sulfamethoxazole are of moderate risk in both water and sediment samples; clarithromycin is of moderate risk in sediment and low risk in water; and ciprofloxacin is potentially of high risk in sediments, but low risk in water.

Across all of the samples analysed, a proportion of compounds were detected below the method LOQs (ca. between 13 and 99 % – [Table](#page-3-0) 1). In the majority of cases, the LOQs permitted comparison of quantified levels with available PNECs for each compound. However, in the case of ciprofloxacin, the LOQ exceeded the PNEC and in only one sample was ciprofloxacin quantified above the LOQ and therefore the PNEC ([Fig.](#page-5-0) 3) though a further 18 % of samples indicated the presence of ciprofloxacin

Table 2

– Risk quotients determined from lowest predicted no-effect concentrations (PNECs) taken from the NORMAN Toxicological Database (as of June 6, 2024) using 95th percentile concentrations (see Section [2.6\)](#page-2-0). QSAR (Quantitative Structural Activity Relationship) utilised for determining PNEC where experimental ecotoxicology value not yet determined. * Based on a single sample which was determined above the LoQ.

above the LOD. Clearly, for ciprofloxacin, a more sensitive analytical method is required to fully assess the environmental risk this compound may present. Overall, results appear to conform with [Monahan](#page-7-0) et al. [\(2022\):](#page-7-0) macrolides such as clarithromycin being of a higher environmental risk compared to fluoroquinolones and trimethoprim. However, sulphonamides were also flagged by this model as being low-risk, though were detected with moderate frequency here (46.2 %) and just below the low-risk threshold based on the calculated MEC₉₅ (0.094). The RQs determined for clarithromycin and Sulfamethoxazole in these sediments may therefore indicate a relatively low-risk for biota. However, further environmental assessments would be beneficial investigating regional hotspots which may be of higher concern for biota, particularly for clarithromycin due to its ubiquity in sediments.

3.4. Comparison of concentrations of antibiotics in Irish and international sediments

[Table](#page-5-0) 3 compares antibiotic concentrations recorded in this study

Fig. 2. Box plot of individual Risk Quotients (RQ) for individual samples (ciprofloxacin omitted for clarity; see [Fig.](#page-5-0) 3 for plot including ciprofloxacin). Blue shaded bars with central black lines denote the median and interquartile range (IQR); lower whiskers denote minimum values; upper whiskers denote [1.5 \times IQR]; open circles denote outliers (*>*1.5 × σ); stars denote extreme outliers (*>*3 × σ); solitary bars denote single value detected above LOQ.

Fig. 3. Box plot of individual Risk Quotients for individual samples (including ciprofloxacin sample). Blue shaded bars with central black lines denote the median and interquartile range (IQR); lower whiskers denote minimum values; upper whiskers denote [1.5 \times IQR]; open circles denote outliers ($>1.5 \times$ σ); stars denote extreme outliers ($>3 \times \sigma$); solitary bars denote single value detected above LOQ.

Table 3

Comparisons of mean antibiotic concentrations (ng/g) in Irish sediments with similar studies conducted worldwide. Note that Levofloxacin and Difloxacin are omitted as suitable data for comparison could not be located. (a) Year stated denotes the collection date as opposed to journal publication date. with those in sediments elsewhere. Within the EU, Ireland appears to be on the lower range of reported antibiotic concentrations in sediments, with the notable exception of clarithromycin which was detected at higher average concentrations than in comparable studies and with a high detection frequency (Ireland – 89.7 %, $n = 80$; Italy – 11.5 %, $n =$ 26; Spain – 75.0 %, n = 20; and France – 100 %, n = 12). The French and Spanish studies were conducted 15 years ago and, globally antibiotic usage has increased by approximately 46 % between 2000 and 2018 ([Browne](#page-6-0) et al, 2021); therefore, concentrations in sediments have likely risen concomitantly. Concentrations in Ireland appear to be at the lower end of those reported worldwide with only Spain and the USA being lower, again with the caveat that increasing use of antimicrobials worldwide during that period may affect that comparison. Internationally, a greater focus is placed on the fluoroquinolones and sulphonamides, with Roxythromycin being the only macrolide to be regularly assessed in these studies (of the antibiotic residues included herein). Though reliable statistics on the market share of antibiotic classes is not available, the variances observed in [Fig.](#page-6-0) 4 indicates that significant inter-regional differences in the environmental uptake – and therefore environmental risk – exist. This is likely based on regional requirements for example: the use of macrolides to treat pneumonia (One [Health](#page-7-0)

[Trust,](#page-7-0) 2012; [Hinnerskov](#page-7-0) et al., 2011) in more affected areas such as Ireland and Argentina ([Dadonite](#page-7-0) and Roser, 2019); the reportedly high use of macrolides in France ([Adriaenssens](#page-6-0) et al., 2021; Le [Baron](#page-7-0) et al., [2024\)](#page-7-0); and the use of fluoroquinolones in swine [\(Hayer](#page-7-0) et al, 2022), and China's dominance of the global pork production market ([USDA,](#page-7-0) 2024). This therefore highlights the need for targeted regional assessments and monitoring of antibiotics based on regional usage.

4. Conclusions

Overall, concentrations of antibiotics in Irish sediments appear to be at the lower end of those detected in similar studies worldwide, with the exception of clarithromycin, which is present at higher concentrations than hitherto reported internationally. Clarithromycin was by far the most frequently detected antibiotic in this study. Lower concentrations of antibiotics were found in sediments isolated from wastewater emission points and low population centres. In contrast, higher concentrations were found in samples directly adjacent to wastewater emission points, and could potentially be attributed to certain specific regional activities such as agriculture, aquaculture, and dairy processing. Based on the concentrations found and available sediment PNECs, most

Fig. 4. Comparisons of mean concentrations of antibiotics in Irish sediments with similar studies conducted worldwide. Values above the bars represent total average antibiotic concentrations quantified in each study. Citations given in [Table](#page-5-0) 3.

antibiotics assessed here appear to present low ecotoxicological risk in terms of their measured concentrations in sediments, with the exception of clarithromycin, sulfamethoxazole, and, potentially, ciprofloxacin (for which the method limit of quantification exceeded the PNEC). This does not however necessarily indicate that other antibiotics are of low environmental risk overall, as the partitioning behaviour of these antibiotics into different matrices highlight that different environmental compartments may be at greater risk depending on the individual compounds. Future monitoring programmes should therefore focus on those antibiotics shown here to be of moderate or high ecotoxicological risk, while taking care to consider the risks of individual compounds in different environmental compartments.

Acknowledgements

This project is funded under the EPA Research Programme

2021–2030 (2021-HE-1056) and co-funded by the Department of Agriculture, Food and the Marine. The EPA Research Programme is a Government of Ireland Initiative funded by the Department of Communications, Climate Action, and Environment. The authors would like to thank the Marine Institute and Uisce Éireann for access to samples required for the completion of this project. The authors would also like to thank Dr Liam Morrison at the University of Galway's School of Natural Sciences, as well as Ronnie Snijder and Tim Mackie of the Norther Ireland Department of Agriculture, Environment, and Rural Affairs' Marine and Fisheries Division, for their assistance in processing samples. Finally, we wish to thank the members of the project's Steering Committee for their invaluable advice and assistance throughout the project's lifetime.
